

Intro & State Variables

A video discussing all of this material is available here: <https://youtu.be/4XQzH8U5eK>

variables declared outside a function are state variables, they are stored on the blockchain when they are **public**

variables declared inside a function are only available during a call of that function, and such variables are not stored on the blockchain

Smart contracts can be written and deployed to a test environment here: <https://remix.ethereum.org> The site cookies save your work

STEP 1: Write a smart contract in this file explorer

STEP 2: Compile the smart contract with compiler version compatible with **0.5.1**

STEP 3: Deploy the smart contract here - to see how it can be accessed on the blockchain with these options **here**

NOTE: If you hold down both Left-Alt and Left-Shift at the same time, you can make the terminal font larger or smaller with the mouse wheel

Taking the public statement out of the state variable will cause you to lose the text button on the blockchain

Variables in Solidity are stored in one of these three locations

storage - this is where data can be permanently stored; these are state variables

memory - variables in memory are only available when the function is executing

calldata - special data location that contains the function arguments, only available for external function call parameters

Types of Functions in Solidity

ones that create transactions

ones that do not create transactions

Functions that create transactions write data on the blockchain by changing the value of a state variable, which in turn either changes the state of the smart contract, or sends Ether (ETH) to another account, which in turn changes the balance of accounts recorded on the blockchain

Functions that do not create a transaction on the blockchain are free to call (require no gas) and they do not change the state of the blockchain

This function has a single input of type **string**; for certain data types, you have to specifically declare the data location (here it must be **memory** because we (the users) are assigning the **text**)

the actual value stored in the **text** variable; not the reference to the variable, so we will declare it as **memory**

We need to declare the data location for our string type variable **text**; our text variable is stored in a contract storage, but need the actual value stored in the **text** variable; not the reference to the variable, so we will declare it as **memory**

this function will update the state variable

The convention in Solidity is to prefix a function input variable with an underscore **_text** so as to avoid using the same names as state variables

If a function returns a value, it needs **return** keyword in the function definition

view ensures that your function does not change the state of the blockchain, **pure** declares that your function neither changes the state of the blockchain nor does it read any state variables

When you want to return multiple values from a single function call you will use this option

Otherwise use this option

This example shows a state variable (of type string) called **text** as well as a get function that returns the value of the same text variable; You would actually choose one of these two options but you do not need both!

Ether and Wei

A video discussing all of this material is available here: <https://youtu.be/ybPQsjuXW>

The currency used within Ethereum is Ether; it can be used to:

pay block reward

pay transaction fee

transfer between accounts

The smallest unit of Ether is Wei! 1 Ether is equal to 10¹⁸ Wei

Wei is an unsigned integer which means it cannot have a sign in front of it like "or" or "not" ... this means that the integer cannot be negative

units can only be added after literal numbers; for example, 1 ether is valid whereas x wei is not

Gwei stands for Giga-Wei and is equal to one billion wei; the most common situation where you would see the word Gwei is when you submit a transaction to the blockchain because the transaction, Gwei is used to set the Gas price

If you head over to etherscan.io and look at any of the Latest Transactions, the Gas Price is listed in Gwei

Etherscan

giga-wei

gas

gas price

Transaction (Tx) fee = gas used * gas price (Gwei)

Each thing you do costs gas; the amount of gas required for each computation depends on **what amount miners accept**

In this transaction, we are setting the gas limit to 3,000 and the gas price to 2 gwei, and thus, when this transaction is processed it will cost 6,000 gwei (3,000 x 2)

In abstract terms, let's assume 2 gwei is lower than the current average and we're specifying 2 gwei because we're not in a hurry to have our transaction added to the blockchain

Assuming the transaction computations were such that they cost 1000 gas, then the cost to process (per this) - then the cost would equal 2,000 gwei, and the cost would mean that your account would be refunded 4,000 gwei since you effectively overpaid for the transaction and so the transaction 'cost' isn't the actual amount of gas that this whole thing actually costs you in the end - happens when you overallocate gas

An infinite loop would cost infinity gas to process; let's assume we allocate 6,000 gwei in weight (like we did here) and that each iteration happens to cost 1,800 gwei per supply and demand; here's what would happen

after first iteration (~ 1,800 gwei, 4,200 gas left)

after second iteration (~ 1,800 gas, 2,400 gas left)

after third iteration (~ 1,800 gas, 600 gas left)

after fourth iteration (~ 1,800 gas, 0 gas left)

At every step of function execution gas is deducted until either the function finished execution or all of the gas is used up at which point the execution is avoided

not enough gas

On the fourth iteration it uses up all remaining 600 gas midway through the iteration and then the function is forcefully stopped; any changes that were made to a state variable will be undone; but you still have to pay for the gas spent!

computations

high gas limit = many computations

low gas limit = few computations

tradeoffs

high gas price = short waiting time

low gas price = long waiting time

time

There are two upper-bounds to limit the gas you can spend:

Gas Limit - set by you

Block Gas Limit - set by the network

When you send a transaction to the real Ethereum network you set the gas price, but gas price in remix is fixed at 1 wei, and we can verify that by checking the output of this function

we can see our balance here

we can click here to check the transaction cost

we can change the gas limit here

Invalid Functions

A video discussing all of this material is available here: https://youtu.be/71cmPaD_AnQ

Invalid Inputs & Outputs for Public Functions

map

multi-dimensional arrays (unfixed size)

In Solidity, there are certain data types that cannot be input variables in public functions (e.g. "[]") and there are also data types that are not recommended (e.g. "[]") as well. This is also valid wherever x wei is not allowed and "[]" is not recommended

inputs

If you get rid of this statement and replace it with this statement, then this function will compile; otherwise it will not compile; the other two functions will compile just fine without using this statement. It is not recommended that you use any array as an input variable because different array sizes require different amounts of gas to process, and so sometimes the function will process just fine and other times it will run out of gas when using an array as an input variable

One way to make an array more reliable (as an input variable) and avoid the problem with gas (discussed above) is to put an upper-bound to the array size that will in turn limit the amount of gas consumed

outputs

If we try using **map** and/or **multi-dimensional** arrays, we will also get compile errors

this function will not compile

this function will not compile

Using a one dimensional array with an unfixed size is not recommended because your contract might get called by a second contract and so your contract's function output is another contract's function input; one way to solve this issue is to write functions that have a bounded consumption of gas

In Solidity, you can return multiple values, and these values can also be named; the options on the left are all valid ones

multiple un-named values

multiple named values

explicitly assigned to return variables and omit the last return statement

function that returns multiple functions

We can call **firstFunc** and then call **secondFunc** separately, or we can just call **thirdFunc** instead

the "[]" is a special character that you can only use in a function modifier; it tells Solidity to execute the rest of the code inside the parent function

if the message sender is not the current owner, the transaction fails

You attach a **modifier** to a function by declaring it **here** in the function signature

this modifier prevents recursive calls by first setting the locked to **false**, then when the function is called **here** it sets the locked to **true**, and it starts executing its code **here**, and next it calls **itself** again **here** but since locked is set to **true** at this point, the recursive statement fails **here** and the transaction therefore fails so as to prevent a **reentrancy** hack

function **returnMultipleVals()** and the variable types declared **here** are consistent with the types of values **here** that are being returned by the function being called

If a function returns three parameters, but you don't care about the second one (in this case, the **B**) then you can use destructuring by adding in an **empty space with a comma** to let Solidity know to skip that value

destructuring assignments

Destructuring assignments can be used to assign variables to the output of a function which returns multiple values

Here we are assigning the outputs of the function **returnMultipleVals()** and the variable types declared **here** are consistent with the types of values **here** that are being returned by the function being called

View and Pure Functions

A video discussing all of this material is available here: <https://youtu.be/kmoALAL8C>

view functions do not modify the state of the blockchain

pure functions do not modify the state of the blockchain, nor do they read the state either

According to the Solidity docs **here**, the following statements are considered modifying the state:

1. Writing to state variables

2. Creating other contracts

3. Using selfdestruct

4. Sending Ether via calls

5. Calling any function not marked view or pure

6. Using low-level calls

7. Using inline assembly that contains certain opcodes

NOTE: this is a function to call when you want to delete your contract from the blockchain

pure makes a stronger statement than view

According to the Solidity docs **here**, the following are considered reading from the state:

1. Reading from state variables

2. Accessing address(this).balance or

3. address().balance

4. Accessing any of the members of block, tx, msg

5. (with the exception of msg.sig and msg.data)

Calling any function not marked pure

Using inline assembly that contains certain opcodes

This is a valid view function because it reads from the state, it could not be a pure function

A view function cannot call another function that is neither view or pure

This is an invalid pure function because pure functions cannot call a non-pure function, even if that function is a view function

This is a valid pure function since it doesn't read and/or modify any state

Function Modifiers

A video discussing all of this material is available here: <https://youtu.be/thADmg9CKPM>

Function Modifiers are used for:

restricting view access

input validation

reentrancy guard

Function modifiers are reusable code that can be attached to a function; this reusable code can be executed **before** or **after** the function itself is executed

When the contract is deployed, it sets the owner to **msg.sender**

the "[]" is a special character that you can only use in a function modifier; it tells Solidity to execute the rest of the code inside the parent function

if the message sender is not the current owner, the transaction fails

You attach a **modifier** to a function by declaring it **here** in the function signature

this modifier prevents recursive calls by first setting the locked to **false**, then when the function is called **here** it sets the locked to **true**, and it starts executing its code **here**, and next it calls **itself** again **here** but since locked is set to **true** at this point, the recursive statement fails **here** and the transaction therefore fails so as to prevent a **reentrancy** hack

function **returnMultipleVals()** and the variable types declared **here** are consistent with the types of values **here** that are being returned by the function being called

If a function returns three parameters, but you don't care about the second one (in this case, the **B**) then you can use destructuring by adding in an **empty space with a comma** to let Solidity know to skip that value

destructuring assignments

Destructuring assignments can be used to assign variables to the output of a function which returns multiple values

Here we are assigning the outputs of the function **returnMultipleVals()** and the variable types declared **here** are consistent with the types of values **here** that are being returned by the function being called
